(Received 1 December 2004; published 27 April 2005)

We present a novel, real-time, experimental technique for linear and nonlinear Brillouin zone spectroscopy of photonic lattices. The method relies on excitation with random-phase waves and far-field visualization of the spatial spectrum of the light exiting the lattice. Our technique facilitates mapping the borders of the extended Brillouin zones and the areas of normal and anomalous dispersion within each zone. For photonic lattices with defects (e.g., photonic crystal fibers), our technique enables far-field visualization of the defect mode overlaid on the extended Brillouin zone structure of the lattice. The technique is general and can be used for photonic crystal fibers as well as for periodic structures in areas beyond optics.

Very often, the characteristics of waves propagating in periodic structures are best described in momentum space. While waves in periodic structures occur throughout science, photonic systems have the advantage that optical inputs can easily be manipulated and results can be directly imaged. Moreover, optics provides many technologically important systems relying on the dynamics in periodic structures, such as photonic crystals [1–3], photonic crystal fibers [4–6], and waveguide arrays [7]. The periodicity partitions the linear transmission spectrum of waves in such structures into bands of propagating (Bloch) modes separated by forbidden gaps. The lattice geometry, and the corresponding wave dynamics, is most efficiently presented in the reciprocal (momentum) space through the extended Brillouin zone (BZ) map [8], whose boundaries are defined by the Bragg-reflection planes. For example, Fig. 1(a) shows the first and second Brillouin zones of a square lattice with the high-symmetry points (Γ , X , and M) marked by white dots. Within each band, the curvature of the transmission spectrum varies with the spatial frequency (transverse momentum) and changes sign. This results in regions of normal and anomalous dispersion or diffraction in exactly the same way as band curvature causes positive and negative effective mass in solid-state physics. The first two bands in the transmission spectrum of a square lattice are shown in Fig. 1(b), with the dispersion curves between the symmetry points of the first two bands plotted in Fig. 1(c).

The equivalence between optical waves in a periodic dielectric structure and electrons in a periodic atomic potential has opened up the areas of “Bloch wave optics” [9] and “photonic band gap engineering” [2]. For example, photonic crystals can exhibit a gap in the electromagnetic spectrum: a range of frequencies at which light cannot propagate. In a similar vein, Bragg diffractions from such structures give rise to omnidirectional mirrors reflecting all incident waves within a wide angular range, manifesting a

gap in the spatial transmission spectrum [10]. These ideas, combined with a dielectric defect embedded in the periodic structures, have allowed the fabrication of photonic crystal fibers [11] and photonic band gap lasers [12]. In nonlinear photonic lattices, the defect can be self-induced, leading to the formation of lattice solitons [13–15]. Nonlinearity also serves to couple linear modes, making nonlinear photonic systems excellent platforms to study (image) fundamental problems in lattice dynamics.

Here, we present a novel experimental technique for linear and nonlinear Brillouin zone spectroscopy of photonic lattices. Our technique facilitates a direct visualization of the lattice structure in Fourier space by mapping the borders of the extended BZs, and marking the areas of

normal and anomalous dispersion within them. The method relies on excitation of the lattice modes with partially incoherent waves, performing an optical Fourier transform, and measuring the power spectrum. The technique is general and can be used for any periodic structure. We experimentally demonstrate it on square and hexagonal waveguide arrays, and also study 2D waveguide arrays with positive and negative defects embedded in their structure (equivalent to solid-core and hollow-core photonic crystal fibers, respectively). The method provides a powerful diagnostic tool for photonic lattices. Equally important, our technique points the way towards future experiments on nonlinear mode coupling which have been intriguing scientists since the pioneering work of Fermi, Pasta, and Ulam in 1955 [16].

To map out the momentum space of a lattice, the lattice should be probed by a broad spectrum of its eigenmodes (Bloch waves) in the mapped region of k space. Preferably, one would like to excite the lattice with a broad and uniform spectrum of Bloch modes, residing in several different bands. At the same time, the probe beam must also be broad enough in real space to sample a large enough number of unit cells. These requirements can be reconciled simultaneously by a random-phase (spatially incoherent) probe beam, which facilitates homogeneous excitation of several BZs with a beam that occupies numerous lattice sites. Moreover, the time-averaged intensity of such an incoherent probe beam, which excites many Bloch modes, is smooth because the speckles are washed out. For these reasons, we probe the photonic lattices with a partially spatially incoherent (random-phase) beam, which has a uniform spatial power spectrum extending over several BZs, and is broad enough to cover numerous lattice sites.

Our experiments are carried out in optically induced photonic lattices [14], formed in a highly anisotropic photosensitive nonlinear crystal, utilizing the methods that have recently proven to be very successful for spatial soliton experiments in photonic lattices [14,17,18]. The experimental setup is shown in Fig. 1(d). In all experiments, we use a quasimonochromatic 488 nm laser source, with a temporal coherence length of 3 cm. The 2D square lattice is induced by interfering two pairs of plane waves in the nonlinear material, while the hexagonal (trigonal) lattice is induced by interfering three plane waves under similar conditions (Fig. 2). In both cases, the lattice-forming waves are polarized so as to propagate linearly in the nonlinear medium, serving only to induce the periodic photonic structure. The probe beam (taken from the same laser) is polarized perpendicular to the lattice-forming waves, thus experiencing the periodic index modulation induced by the lattice waves. In addition, at sufficiently high intensities the probe beam propagates nonlinearly in the lattice, undergoing self-focusing or defocusing (as determined by the applied field). Our probe beam is made partially spatially incoherent by passing it through a rotating diffuser, and the power spectrum of the

emerging beam is controlled using a filter in the focal plane of a lens. The laser beam exiting the diffuser is imaged onto the input face of the nonlinear crystal in which the photonic lattice is induced. The optical path difference between the probe beam and the lattice-forming waves is made to greatly exceed the coherence length of the laser, so as to eliminate any residual interference effects between the probe and the lattice waves. The beam is propagating through 5 mm of the waveguide array. Our data are taken by photographing the intensity distribution at the focal plane of the “exit lens,” positioned so as to visualize the Fourier power spectrum of the light exiting the lattice.

Consider first the linear scheme for mapping the extended BZ of square and hexagonal lattices, both with a $\sim 10 \mu\text{m}$ period. The probe beam is $25 \mu\text{m}$ FWHM, and its width in k space is engineered to be twice the reciprocal lattice vector, exhibiting the far-field diffraction characteristic of a $\sim 5 \mu\text{m}$ transverse correlation distance. To maximize the contrast of the features in k space, we slightly shift the incidence plane of the waveguide array from the narrowest spot of the entering incoherent beam. Typical results are shown in Fig. 2, where the upper (lower) row depicts experimental data for a square (hexagonal) lattice. The left column, 2(a) and 2(e), shows the interference pattern of the lattice-forming waves, as they exit the crystal. The second column, 2(b) and 2(f), shows the power spectra of the input incoherent probe beam (wide homogeneous circle of illumination) illuminating the lattice, with the far field of the array-forming waves (the sharp peaks) marking the corners of the respective first BZs (the incoming plane waves define the corresponding Bragg angles). The third column, 2(c) and 2(g), shows the textbook calculated picture of the extended BZs of the respective lattices. Finally, the right column, 2(d) and 2(h), shows the experimental far-field picture of the incoherent light emerging from the lattice, depicting the first four BZs of the lattices,

marking the edges of every zone. These experimental pictures form by Bragg reflections from the regions near the boundaries of the BZs of each lattice, resulting in dark stripes in the power spectrum of the probe beam at the boundaries. We emphasize that the probe-beam intensity in these experiments is much lower than the intensity of the array-forming waves ($\sim 1:10$), and no external voltage is applied to the crystal while being probed. Hence, Fig. 2 represents effects caused by linear propagation of the incoherent probe beam in linear photonic lattices.

Next, we examine the spatial transmission spectrum of an incoherent probe beam propagating in a hexagonal (trigonal) lattice with positive and negative defects. The positive defect is created by launching an additional beam (several lattice periods wide), which is copropagating with the array-forming waves but is mutually incoherent with them. Under a positive bias field, this additional beam induces a positive defect in the lattice; i.e., it increases the index of refraction in the region it illuminates. Likewise, a similar beam induces a negative defect when a negative bias field is applied. The upper row in Figs. 3(a)–3(c) depicts the near-field photograph of the array-forming waves and the defect-inducing beam as they exit the nonlinear crystal. The lower row in Fig. 3 shows the (far-field) power spectrum of the probe beam exiting the hexagonal lattice, without a defect 3(d), with a positive defect 3(e), and with a negative defect 3(f), respectively. For the positive defect, the guided modes arise from total-internal reflection of states occupying the central region of the first BZ. The far field of these guided modes appears as a wide spot in the center of the first BZ of Fig. 3(e). On the other hand, for a negative defect (for which the average refractive index is lower in the guiding region), waveguiding arises solely from Bragg reflections, with no contribution from total-internal reflections. As a result, the central region of the BZ picture is empty [not populated; the central “hole” in Fig. 3(f)], and the guided

FIG. 3 (color online). Defect modes in a hexagonal lattice. modes are modes whose momentum arises from the vicinity of the edge of the first BZ [bright concentric ring in Fig. 3(f)].

Finally, when the photonic lattice is nonlinear, the underlying self-focusing (or self-defocusing) interaction among the Bloch states results in energy exchange between these lattice eigenmodes. This feature has been recently observed with random-phase lattice solitons [18], whose power spectra reshape at the first stages of propagation, evolving into the multihump spectra characteristic of such solitons [19]. This interaction facilitates a method for distinguishing between the regions of normal and anomalous diffraction (dispersion) of the underlying lattice and for mapping out the boundaries between dispersion of opposite signs. In these experiments, the probe beam propagates *nonlinearly* in the photonic lattice, and it drives the nonlinear interaction by inducing a broad defect in the lattice structure, which in turn causes energy exchanges between Bloch states. To do this efficiently, the probe-beam intensity must be much higher than in the experiments described by Figs. 2 and 3. In this set of experiments with nonlinear lattices, we use probe-beam intensities which are roughly one-half of the intensity of the lattice-forming array waves. Typical experimental results are shown in Fig. 4. The excitation (far-field) power spectrum of the incoherent probe beam is shown in 4(a). When the crystal is biased with a positive field (self-focusing nonlinearity), the wide probe beam induces a wide (and shallow) positive defect in the lattice. The presence of such a defect causes Bloch waves from anomalous diffraction regions (negative curvature of the band structure) to transfer power to Bloch waves arising from normal diffraction regions. Indeed, Fig. 4(b) clearly reveals the regions of normal diffraction, which have a considerably higher intensity than the low-intensity regions of anomalous diffraction. In a similar fashion, a negative bias field results in a self-defocusing nonlinearity, through which the incoherent probe beam induces a wide negative defect. This negative defect causes energy transfer complementary to that in Fig. 4(b): as shown in Fig. 4(c), regions of anomalous diffraction have significantly higher intensity than regions of normal diffraction.

Experimental Fourier spectrum of the probe beam at the output face of the square lattice under (b) self-focusing nonlinearity and (c) self-defocusing nonlinearity.

To summarize, we have shown two different techniques for linear and nonlinear BZ spectroscopy of photonic lattices, with or without defects. Such defect-bearing lattices are akin to photonic crystal fibers and related waveguiding structures. We have demonstrated our techniques in optically induced lattices; nevertheless, the BZ spectroscopy methods are general and can be used for any periodic optical structure. Both techniques rely on probing the lattice with an incoherent probe beam and visualizing the far-field power spectrum of the light exiting the photonic structure. The linear method relies on Bragg reflections, resulting in dark stripes along the edges of BZs, thus demarcating the k -space lattice structure. The underlying linear mechanism arises from momentum transfer between waves propagating at the close vicinity of the Bragg angles (within the Bragg mismatch), hence the preferential marking of the edges of the various BZs. Our method of *linear* BZ spectroscopy is related to the *Kikuchi patterns* (also known as Kossel lines) that have been observed in atomic structures (crystals) through electron microscopy since the 1920s [20,21]. Similar features have been observed in neutron scattering experiments, also in atomic lattices [22]. Finally, recent experiments in cold atoms in 2D and 3D optical lattices have shown stimulated Raman transition into higher bands, demonstrating some features of the extended BZ map of atomic lattices [23]. However, in that case, the experiments revealed the different populations of the various bands (relying on different band energies), rather than marking the borders between bands through Bragg diffractions (as in our experiments). For this reason, the technique used in cold atoms cannot distinguish between bands that are not separated by a complete gap [23]. Altogether, we emphasize that to the best of our knowledge no such methods for BZ spectroscopy have ever been demonstrated in photonic structures.

In contrast to our linear BZ spectroscopy method (which has similarities to phenomena in electron microscopy and neutron scattering), our *nonlinear method* adds new features that have never been observed in any system. Namely, our *nonlinear* BZ spectroscopy method marks the areas of normal and anomalous dispersion (diffraction, effective mass, etc.) wherever they occur within the BZs of the lattice. This method relies on the nonlinear propagation of the probe beam in the (photonic) lattice. The probe induces (in real time) a broad defect in the lattice, which results in energy exchange between Bloch waves. During a self-focusing interaction, Bloch waves from anomalous diffraction regions transfer power to Bloch waves arising from normal diffraction regions, and vice versa for a self-defocusing interaction. The underlying physics behind the nonlinear energy exchange among Bloch states has been intriguing researchers since the famous Fermi-Pasta-Ulam report [16], and its fine details are still not fully understood. Moreover, our *nonlinear* BZ spectroscopy method most

probably cannot be introduced to electron microscopy or neutron scattering, simply because the latter processes are fundamentally linear. In particular, it would be very difficult to observe nonlinear interactions between electron (or neutron) waves in a crystal and keep the crystalline structure intact. Nevertheless, our nonlinear technique does have immediate relevance to other nonlinear periodic systems (e.g., dynamics in Bose-Einstein condensate, plasma, sound, etc.), many of which are now being explored in the context of “discrete” solitons [15].
