Centrality dependence of charged hadron and strange hadron elliptic flow from \( \sqrt{s_{NN}} = 200 \text{ GeV} \)

Au+Au collisions

Au+Au collisions

\( \sqrt{s_{NN}} = 200 \text{ GeV} \)
We present STAR results on the elliptic flow \( v_2 \) of charged hadrons, strange and multistrange particles from \( \sqrt{s_{NN}} = 200 \) GeV Au+Au collisions at the BNL Relativistic Heavy Ion Collider (RHIC). The detailed study of the centrality dependence of \( v_2 \) over a broad transverse momentum range is presented. Comparisons of different analysis methods are made in order to estimate systematic uncertainties. To discuss the nonflow effect, we have performed the first analysis of \( v_2 \) with the Lee-Yang zero method for \( K^0_S \) and \( \Lambda \). In the relatively low \( p_T \) region, \( p_T \leq 2 \) GeV/c, a scaling with \( m_T - m \) is observed for identified hadrons in each centrality bin studied. However, we do not observe \( v_2(p_T) \) scaled by the participant eccentricity to be independent of centrality. At higher \( p_T \), \( 2 \leq p_T \leq 6 \) GeV/c, \( v_2 \) scales with quark number for all hadrons studied. For the multistrange hadron \( \Omega \), which does not suffer appreciable hadronic interactions, the values of \( v_2 \) are consistent with both \( m_T - m \) scaling at low \( p_T \) and number-of-quark scaling at intermediate \( p_T \). As a function of collision centrality, an increase

2020
of $p_T$-integrated $v_2$ scaled by the participant eccentricity has been observed, indicating a stronger collective flow in more central Au+Au collisions.

I. INTRODUCTION

The event azimuthal anisotropy with respect to the reaction plane has been widely studied in order to evaluate the collective behavior of the matter produced in high-energy nuclear collisions [1–3]. The initial configuration space anisotropy is expected to be self-quenched by expansion and reduced by frequent rescatterings in the hot and dense medium created in such collisions. The final observed momentum space anisotropies, therefore, carry information about the early stage collision dynamics [4–6]. The experimental results of the second harmonic azimuthal anisotropy, elliptic flow, $v_2$, from Au+Au collisions have demonstrated the development of partonic collectivity [7–10]. Further detailed analyses of the hadron mass dependence of $v_2$ suggest that the system has been in the deconfined state with constituent quark degrees of freedom prior to hadronization [11–13]. Furthermore, results of multistrange hadron transverse momentum distributions and $v_2$ indicate that the system reached thermalization at the partonic stage [14–17].

Hydrodynamic model calculations, with the assumption of ideal fluid behavior (no viscosity), have been successful when compared with the experimental data from the BNL Relativistic Heavy Ion Collider (RHIC) [6,8,11,18]. It should be noted that up to now, the discussions of the underlying dynamics of the thermalization at RHIC are inconclusive. Some initial evidence for thermalization was provided by the quantitative calculations and data for identified hadrons $\pi$, $K$, $p$, and $\Lambda$ [11,19] from minimum bias (0–80% centrality) Au+Au collisions [20]. As shown in Refs. [7,8], ideal hydrodynamic model calculations have failed to reproduce the centrality dependence of $\pi$ and $p$ $v_2$ in Au+Au collisions. In addition, the discussion based on the integrated $v_2/\epsilon_{\text{part}}$ of charged hadrons suggests possible thermalization only for the most central collisions at RHIC (see Refs. [21,22] and references therein). Here the participant eccentricity, $\epsilon_{\text{part}}$, is the initial configuration space eccentricity of the participants. From peripheral to the most central Au+Au collisions, the values of $v_2/\epsilon_{\text{part}}$ increase as a function of the scaled charged hadron multiplicity, as predicted by a model calculation assuming the low density limit [23] of single forward nucleon-nucleon collisions. This analysis indicates that the system has probably not reached thermalization for most peripheral Au+Au collisions.

Hydrodynamic model calculations predict a characteristic dependence of the elliptic flow and transverse momentum spectra on particle mass and collision centrality. Nevertheless, the comparisons made so far have been mostly restricted to identified hadrons from minimum bias collisions or integrated $v_2$ of charged hadrons [21]. Systematic comparisons for identified hadrons at different collision centralities are still scarce [8]. To fill this gap and further advance our understanding of the properties of the medium created in high-energy nuclear collisions, in this article we report the centrality dependence of the azimuthal anisotropy parameter $v_2$ (elliptic flow) in $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions. The centrality dependence of $v_2$ for unidentified charged hadrons ($h^+ + h^-$), $K^0_S$, and $\Lambda$ are also reported. In complex nuclear collisions, different systematic errors on $v_2$ can arise from different analysis methods. In this paper, the systematic errors are analyzed by comparing the standard event plane method [2,8] with results from the Lee-Yang zero [25], four-particle cumulant [22,26], and $\eta$ subevent [8] methods.

The paper is organized in the following way: we discuss experimental cuts, data selections, and methods used for unidentified charged hadrons and identified hadrons in Sec. II. Section III gives the results on unidentified charged hadrons and identified hadrons in Sec. II. Section IV presents a comparison with model calculations as well as a discussion of scaling and the systematics of the $v_2(p_T)$ distributions from the CERN Super Proton Synchrotron (SPS) ($\sqrt{s_{NN}} = 17.3$ GeV) and RHIC ($\sqrt{s_{NN}} = 62.4$ and 200 GeV). Finally, the summary of the analysis and the outlook are presented in Sec. V.

II. METHODS AND ANALYSIS

In this paper, if $v_2$ is used without curly brackets it is an abbreviation for $v_2(\text{EP}_2)$, that is, $v_2$ relative to the second harmonic event plane. The systematic uncertainty from the event plane resolution is constant at each centrality and expected to be smaller than that of the observed differential flow, and it is not folded in. Other systematic errors are discussed in Sec. III.

A. Data sets

For this study, the high statistics data from $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions collected by the STAR experiment during RHIC’s fourth year (2004) of data taking were analyzed. STAR’s main time projection chamber (TPC) [27] was used for tracking and identification of charged particles. The TPC records the hits used for reconstruction of the tracks of the particles, enabling the measurement of the momenta of the particles, and the identification of the particles by measuring their ionization energy loss. The TPC provides complete azimuthal coverage and complete tracking for charged particles within $\pm 1.3$ units of pseudorapidity. The two forward time projection chambers (FTPCs) cover two sides of the collision with $2.5 < |\eta| < 4.0$. The FTPCs also provide a tool for studying nonflow effects. About $25 \times 10^6$ minimum bias events (0–80% most central of the hadronic interaction cross section) were analyzed, which increased the statistics for flow...
which are bin from \( p^+ \) measurements \([8,10,12]\).

B. I. ABELEV was enhanced by online triggering on the most central events bins, which were central (0–10%), midcentral (10–40%), and peripheral (40–80%). In addition, the central dataset (0–10%) was enhanced by online triggering on the most central events with the zero-degree calorimeter (ZDC) \([28]\), thereby getting an additional \( \sim 19 \times 10^6 \) events for a similar centrality bin. Within the statistical uncertainty, the results from the central trigger dataset were consistent with those from the minimum bias trigger.

The analyzed charged particles were identified as the track helix in the TPC magnetic field. The charged tracks were selected with a transverse momentum range of 0.15 \( < p_T \) \( < 2 \) GeV/c unless indicated otherwise, and a pseudorapidity range of \( |\eta| < 1.0 \). For the Lee-Yang zero product generating function analysis, the \( \eta \) interval increased to \( |\eta| < 1.3 \) in order to obtain more particles. A minimum of 15 track fit hits and a ratio of hits to maximum possible hits of \( >0.52 \) was also required. To improve the selection of good tracks from the primary collisions, the distance of closest approach of the analyzed tracks to the event vertex had to be less than 2 cm. Tracks of charged daughter particles stemming from weak decay, which tend to be at large distances, are not subject to this cut.

**B. Particle identification**

We identified \( K_S^0, \Lambda, \Xi^-, \Xi^+ \), and \( \Omega^- (\Omega^+) \) through their decay channels: \( K_S^0 \rightarrow \pi^+ + \pi^- \), \( \Lambda \rightarrow p + \pi^- (\Lambda \rightarrow \bar{p} + \pi^+) \), \( \Xi^- \rightarrow \Lambda + \pi^- (\Xi^- \rightarrow \Lambda + \pi^+) \), and \( \Omega^- \rightarrow \Lambda + K^- (\Omega^- \rightarrow \Lambda + K^+) \). The charged pions, kaons, and protons were identified via their energy loss in the TPC \([27]\).

According to the (multi)strange particle decay properties, topological cuts and kinematic cuts were applied to reduce the combinatorial background. The detailed description of the analysis method can be found in Refs. \([10,29]\) for \( K_S^0 \) and \( \Lambda \), and in Refs. \([12,30]\) for \( \Xi \) and \( \Omega \).

Figure 1 shows the invariant mass distributions for (a1) \( K_S^0 \), (b1) \( \Lambda + \bar{\Lambda} \), (c1) \( \Xi^- + \Xi^+ \), and (d1) \( \Omega^- + \Omega^+ \) for a given \( p_T \) bin from \( \sqrt{s_{NN}} = 200 \) GeV minimum bias (0–80%) Au+Au collisions. Clear signal peaks are seen at the values expected for the particle mass above the combinatorial background. The measured invariant mass distributions contain both signal (Sig) and combinatorial background (Bg). For \( K_S^0 \) and \( \Lambda \), the measured invariant mass distributions were fitted by a polynomial (up to fourth order), which represents the background, and a double-Gaussian function, which represents the signal. The double-Gaussian was used because of tails on the distribution. For multistrange baryons \( \Xi \) and \( \Omega \), the Bg was estimated by rotating the transverse momentum of the daughter \( \Lambda \) by 180°. This operation breaks the correlation between the \( \Lambda \) and the other daughter particle. The resulting invariant mass distributions provide a good approximation of the true background distribution. The detailed description of the method can be found in Ref. \([12]\).

For \( v_2 \) the identified particles, \( K_S^0, \Lambda \), and \( \Xi^- + \Xi^+ \), and \( \Omega^- + \Omega^+ \), the \( v_2 \) versus \( m_{inv} \) method is used in this analysis \([31]\). Since \( v_2 \) is additive, one can write the total \( v_2^{Sig+Bg} \) as a sum of Sig and Bg contributions weighted by their relative yields:

\[
v_2^{Sig+Bg}(m_{inv}) = v_2^{Sig} \frac{Sig}{Sig + Bg}(m_{inv}) + v_2^{Bg}(m_{inv}) \frac{Bg}{Sig + Bg}(m_{inv}). \tag{1}
\]

This method involves the calculation of \( v_2^{Sig+Bg} \) as a function of \( m_{inv} \) and then fitting the distribution using Eq. (1) with measured relative yields and parametrizations of \( v_2^{Sig} \) and \( v_2^{Bg}(m_{inv}) \). The \( \frac{Bg}{Sig+Bg}(m_{inv}) \) distribution is the Bg divided by (Sig + Bg). The \( \frac{Sig}{Sig+Bg}(m_{inv}) \) distribution is simply calculated by \( 1 - \frac{Bg}{Sig+Bg}(m_{inv}) \). The term \( v_2^{Bg}(m_{inv}) \) is parametrized as a linear function in order to take care of the nonconstant \( v_2^{Bg} \) value as a function of \( m_{inv} \). The fit result \( v_2^{Sig} \) is the final observed \( v_2 \). The fit results for \( K_S^0, \Lambda \), and \( \Xi^- + \Xi^+ \), and \( \Omega^- + \Omega^+ \) are shown, as dot-dashed lines, in Figs. 1(a2), 1(b2), 1(c2), and 1(d2), respectively. Note that the anisotropy varies as a function of \( p_T \) and hadron mass. In this figure, the \( v_2 \) are shown for different hadrons with the \( p_T \) cuts listed in the caption. How this method works well for measuring signal \( v_2 \) is explained as follows: a set of data points is used in the fit over a wide \( m_{inv} \) region for Sig and Bg. Data points far from the mass peak constrain \( v_2^{Bg}(m_{inv}) \), since pure Bg is expected in this region. [The disagreement at \( m_{inv} \sim 1.29 \) GeV/c\(^2 \) in Fig. 1(c1) is caused by misidentified hadrons in the \( \Lambda \)-pion combinations, which is explained in Ref. \([12]\).] Under the peak, the \( v_2^{Sig+Bg}(m_{inv}) \) is dominated by the Sig distribution. Finally, the \( v_2 \) signal is extracted by the fitting method shown in Eq. (1).

The results obtained with this technique are in good agreement with the ones from the method used previously \([2]\). Note that the subtraction procedure used to extract the \( v_2 \) signal for a given identified particle is independent of the flow correlations. The \( v_2 \) distributions of the overall signal and background are evaluated by a specific flow analysis method. These methods will be discussed in Sec. II C.

**C. Flow analysis methods**

The systematic uncertainty of the event plane method is evaluated by comparing the results to those obtained by other techniques for measuring anisotropic flow. The various methods have different sensitivities to nonflow effects and \( v_2 \) fluctuations, and such studies provide information on the magnitude of the systematic uncertainty. Nonflow effects are correlations not associated with the reaction plane and include resonance decays, HBT correlations, final state interactions, and jets, to the extent that they do not participate in the flow.
1. Event plane method

The essence of the event plane method [2] is to first estimate the reaction plane. The estimated reaction plane is called the event plane and is determined by the anisotropic flow itself for each harmonic of the Fourier expansion of the anisotropic flow. The event plane resolution is obtained from the correlation of the event planes of two subevents. The event plane resolution for the subevents with the assumption of pure flow correlations between the subevents is

\[
\langle \cos (2 (\phi^A - \Psi_r)) \rangle = \sqrt{\frac{\langle \cos (2 (\phi^A - \Psi_r^B)) \rangle}{\langle \cos (2 (\Psi_r^A - \Psi_r)) \rangle}},
\]

where brackets denote an average over a large event sample, and \(\Psi_r\) is the angle of the reaction plane. The event plane resolution is estimated by the correlation of the event planes of two subevents. The event plane resolution for the subevents with the assumption of pure flow correlations between the subevents is

\[
\langle \cos (2 (\phi^A - \Psi_r)) \rangle = \frac{\langle \cos (2 (\phi^A - \Psi_r^B)) \rangle}{\langle \cos (2 (\phi^A - \Psi_r)) \rangle},
\]

where \(A\) and \(B\) denote two subgroups of tracks. In this analysis, we use two random subevents with equal numbers of particles. Further, the full event plane resolution is obtained from the resolution of the subevents:

\[
\langle \cos (2 (\phi^A - \Psi_r)) \rangle = C \langle \cos (2 (\phi^A - \Psi_r)) \rangle,
\]

where \(C\) is a constant calculated from the known multiplicity dependence of the resolution [2]. In the case of low resolution (<0.5), \(C\) is equal to \(\sqrt{2}\). The actual event plane resolutions for the centrality bins used in this analysis of 0–10%,
2. \( \eta \)-subevent method

The \( \eta \)-subevent method attempts to reduce the contribution from nonflow effects (mostly due to short-range correlations) by correlating particles separated in pseudorapidity. This technique is similar to the event plane method, except one defines the event flow vector for each particle based on particles measured in the opposite hemisphere in pseudorapidity:

\[
v_2(\eta_\pm) = \frac{\langle \cos(2(\phi_{\eta_+} - \Psi_{2,\eta_0})) \rangle}{\sqrt{\langle \cos(2(\Psi_{2,\eta_+} - \Psi_{2,\eta_-})) \rangle}}. \tag{9}
\]

Here \( \Psi_{2,\eta_+} \) (\( \Psi_{2,\eta_-} \)) is the second harmonic event plane angle defined for particles with positive (negative) pseudorapidity. An \( \eta \) gap of \( |\eta| < 0.075 \) between positive and negative pseudorapidity subevents is introduced to guarantee that nonflow effects are reduced by enlarging the separation between the correlated particles. In Eq. \( (9) \) the nonflow effects (correlations) are reduced in both the observed flow (numerator) and the event plane resolution (denominator). Depending on the nature of the remaining nonflow effects, \( v_2 \) measured this way may have values that are either lower or higher than those obtained with the standard method.

3. Four-particle cumulant method

A method to calculate \( v_2 \) from true four-particle correlations was developed in Ref. [26] and has already been used by STAR [22]. It utilizes the second-harmonic flow vector \( \vec{Q}_2 \) measured this way may have values that are either lower or higher than those obtained with the standard method.

\[
C[4] = \langle u_{n,1}u_{n,2}u_{n,3}^*u_{n,4}^* \rangle - 2 \langle u_{n,1}u_{n,2}^* \rangle \langle u_{n,3}u_{n,4}^* \rangle = -v_4[4], \tag{10}
\]

where \( u_{n,j} = e^{i\phi_j} \). The cumulant allows one to subtract the two-particle correlations, including two-particle nonflow, from the four-particle correlations. In practice, cumulants are calculated using the generating function from Ref. [26] and described in Ref. [22]:

\[
G_\theta(z) = \prod_{j=1}^{M} \left( 1 + \frac{z^* u_{n,j} + z u_{n,j}^*}{M} \right), \tag{11}
\]

where \( z \equiv |z| e^{i\alpha} \) is an arbitrary complex number, with \( z^* \) denoting its complex conjugate. The cumulants are related to the generating function by

\[
M((G_\theta(z))^{1/M} - 1) = \sum_{k} \left| \frac{z^{2k}}{(k!)^2} \right| C[2k], \tag{12}
\]

The fit to the \( C[4] \) term is needed. The fourth root of the negative of it gives \( v_2[4] \).

4. Lee-Yang zero method

The Lee-Yang zero method [24,25] is based on a 1952 proposal of Lee and Yang to detect a liquid-gas phase transition. As opposed to the four-particle cumulant method, this method is sensitive to the correlations of all the particles. Thus it is supposed to remove nonflow correlations to all orders. It has so far been used only to analyze one set of experimental data [32] and one set of transport calculations [33]. The method utilizes the second-harmonic flow vector \( \vec{Q}_2 \) and the average is taken over all events. When data are analyzed in small batches, the \( G_\theta(r) \) histograms are combined before finding the first minimum. Such a histogram is shown in Fig. 2(a). The square of the modulus is used to determine the first minimum. The position along the imaginary axis of the first minimum of the modulus of the generating function along the imaginary axis is used. The sum generating function based on \( Q_2^\theta \) is given by

\[
G_\theta^2(i r) = |\langle e^{i r Q_2^\theta} \rangle|, \tag{14}
\]

where \( r \) is a variable along the imaginary axis of the complex plane, and the average is taken over all events. When data are analyzed in small batches, the \( G_\theta^2(r) \) histograms are combined

\[
P_{v_2} = \frac{j_{01}/r_0}{M}, \tag{15}
\]

\[
v_2 = \sqrt{P_{v_2}/M}, \tag{16}
\]

where \( j_{01} = 2.405 \) is the first root of the Bessel function \( J_0 \), and \( M \) is the multiplicity. In the second equation, the average is taken over the laboratory angles \( \theta \). However, Eq. \( (16) \) is only valid for unit weights. Normally, the anisotropic flow parameter averaged over \( p_T \) and \( \eta \) is obtained by taking the yield-weighted average of the differential flow. For unit weights, this has been shown to agree with the “integrated” flow from Eq. \( (16) \). The differential flow obtained by a second pass through the data is given by

\[
v_{2m}^\theta(\eta, p_T) = \frac{J_m(j_{01})}{J_m(0)} \text{Re} \left( \frac{\langle \cos(2m(\phi_j - \theta)) \rangle}{i^{m-1} Q_2^\theta} \right), \tag{17}
\]

where \( m = 1 \) for \( v_2 \) and \( m = 2 \) for \( v_4 \). The average in the numerator in the first equation is over the particles of interest, and the average in the denominator is over all events.

The product generating function is

\[
G_\theta^2(i r) = \left| \prod_{j=1}^{M} [1 + i r w_j \cos(2(\phi_j - \theta))] \right|. \tag{18}
\]
This takes more computer time, because the product over all particles has to be calculated for each value of $r$. An example is shown in Fig. 2(b). It can be seen that the sum generating function oscillates after the first minimum, but the product generating function rises very fast. Thus, for the product generating function, the calculation was halted when $|G_{\theta}^2(ir)|^2$ got larger than 1000. This happened at various $r$ values between 0.2 and 0.4. While the method using the sum generating function is slightly faster than the standard method [2], using the product generating function is about four times slower. For the product generating function, Eqs. (15) and (16) still hold, but the differential flow is given by

$$v_2 m(\eta, p_T) = v_2 J_2(\tilde{j}_0) \sum_j \frac{G_{2}^{R}(ir\theta)|_{1 + ir\theta_0} \cos[2(\phi_j - \theta)]}{1 + ir\theta_0} \cos(2\phi_j - \theta) \right) \left( \frac{G_{2}^{R}(ir\theta)|_{1 + ir\theta_0} \cos[2(\phi_j - \theta)]}{1 + ir\theta_0} \cos(2\phi_j - \theta) \right),$$

where again the average in the numerator is over the particles of interest, and the average in the denominator is over all events. Although the sum generating function works fine for $v_2$, analyses for $v_4$ (and $v_1$) have to be based on the product generating function [25]. This is because the product generating function is better at suppressing autocorrelation effects, which are more important for mixed harmonics. All methods used in this paper have been tested on simulated data. Also, since drift of the beam in the detector over time might simulate the effect of anisotropic flow, run-by-run recentering of the $Q$ vector was applied but produced no improvement in the results.

The errors were calculated from the variation of the results for different event subsamples. For very large errors, this technique could underestimate the error because even when there is no flow the method will find a minimum from a fluctuation. In fact, the Lee-Yang zero method only works for sufficient signal-to-noise ratio. Since the signal is $v_2$ and the noise is proportional to $1/\sqrt{M}$, the parameter $\chi = v_2/\sqrt{M}$ determines the applicability of the method. We find that the errors get large and the results scatter when $\chi < 0.8$, and thus the results are presented here only for 10–50% centrality. The method fails for more central collisions because $v_2$ is small, and for more peripheral collisions because the multiplicity is small.

III. RESULTS

A. Charged hadrons

To evaluate the different flow analysis methods and to estimate systematic uncertainties, charged hadrons were analyzed first. Figure 3 shows $v_2(\eta)$ for both the Lee-Yang zero and

FIG. 3. (Color online) $v_2$ for charged hadrons from the Lee-Yang zero product generating function (solid circles) and from the event plane method (open circles), as a function of pseudorapidity. The PHOBOS data (10–40%) [35] (crosses) are also shown. The error bars are shown only for the statistical uncertainties.
event plane methods. For the event plane method, the event plane was taken from the main TPC, for tracks in both the TPC and the FTPC. For the Lee-Yang zero method, where there is no event plane, tracks in all three TPCs were used. The Lee-Yang zero results are for the product generating function but are in agreement with the sum generating function results. Elliptic flow falls off in the FTPC covering $|\eta|$ from 2.6 to 4.2. This falloff probably occurs because the spectra as a function of $p_T$ are steeper at high $\eta$ and give less weight to the large $v_2$ values at high $p_T$ [34]. Agreement in the FTPC region between two-particle and multiparticle methods has been seen previously [8]. Having a gap in pseudorapidity between the particles being correlated reduces the nonflow effects due to short-range correlations. Indeed, the PHOBOS Collaboration correlates particles with an event plane from a different part of their detector, which is essentially similar to the $\eta$-subevent method. With $|\eta| \leq 1$, PHOBOS [35] data points are consistent with STAR Lee-Yang zero data, although it appears that PHOBOS data may be more peaked. Averaging over the TPC $\eta$ region $|\eta| < 1.0$, the $v_2(p_T)$ values are shown in Fig. 4(a) together with event plane and four-particle cumulant results. For these charged hadrons, the ratio of the four-particle cumulant result to the event plane method shown in Fig. 4(b) falls off as $p_T$ increases. This indicates a nonflow effect in the event plane method which increases with $p_T$ as one would expect for the contribution of jets. On the other hand, the Lee-Yang zero ratio seems to be flat. Figure 5(a) shows the integrated $v_2$ (averaged over $\eta$ and $p_T$) for four different analysis methods as a function of centrality. The ratios to the event plane method are shown in Fig. 5(b). The centrality region where all methods have reasonable error bars is 10–50%. The event plane method appears to be about 15% higher than the other methods known to greatly reduce nonflow effects. This effect was already seen in the differential data as a function of $\eta$ for $p_T < 2$ GeV/c in Fig. 3 and as a function of $p_T$ in Fig. 4. For the most peripheral collisions, nonflow might be larger; and for the most central collisions, fluctuations could be important. From Fig. 5, we would estimate the systematic errors at these other centralities to be 20% and probably this same value for minimum bias events.

B. $K^0_L$ and $\Lambda$

To estimate the particle dependence of systematic errors, $K^0_L$ mesons and $\Lambda$ baryons were analyzed with different flow analysis methods. Figure 6 shows 10–40% $v_2(p_T)$ of (a) $\Lambda + \bar{\Lambda}$ and (b) $K^0_L$ obtained with the event plane, Lee-Yang zero, and $\eta$-subevent methods. Ratios of $v_2$ from these various methods to the event plane method are shown in Figs. 6(c) and 6(d) for $\Lambda + \bar{\Lambda}$ and $K^0_L$, respectively. The results from the Lee-Yang zero method are about 10% lower than those from the event plane method. This is consistent with charged particles, indicating that nonflow effects for $K^0_L$ and $\Lambda$ are also reduced in the Lee-Yang zero method. However, the ratio of the Lee-Yang zero to event plane method appears to be flat up to 5 GeV/c, considering the large statistical uncertainties. This is again similar to the trend observed for charged-particle Lee-Yang zero results, which are shown as shaded bands. The results for the $\eta$-subevent method are higher.
FIG. 6. (Color online) \( v_2 \) as a function of \( p_T \) for 10–40% centrality using event plane method (open circles), Lee-Yang zero method with sum generating function (solid circles), and \( \eta \)-subevent method (open crosses) for (a) \( \Lambda \) and (b) \( K^0_S \). All data are from \( \sqrt{s_{NN}} = 200 \) GeV Au+Au collisions. The ratios \( v_2\{\text{LYZ}\}/v_2\{\text{EP}\} \) and \( v_2\{\eta\}/v_2\{\text{EP}\} \) are shown for (c) \( \Lambda \) and (d) \( K^0_S \). The \( v_2\{\text{LYZ}\}/v_2\{\text{EP}\} \) ratios for charged hadrons are shown as shaded bands. Error bars are shown only for the statistical uncertainties.

D. Other systematic uncertainties

To estimate the systematic uncertainties in the identified hadron \( v_2 \), we employed the standard event plane method, the \( \eta \)-subevent method, and the Lee-Yang zero method. The results of the analysis for \( \Lambda + \bar{\Lambda} \) and \( K^0_S \) are shown in Fig. 6. The ratios to the event plane results are shown in the lower panels. We limited ourselves to the 10–40% centrality bin where the results from the Lee-Yang zero method are most reliable. For comparison, the charged hadron results from the \( v_2\{\text{LYZ}\}/v_2\{\text{EP}\} \) ratios (Fig. 4) are also shown in the figure as shaded bands. There is no clear \( p_T \) dependence of the ratio \( v_2\{\text{LYZ}\}/v_2\{\text{EP}\} \) for either \( \Lambda + \bar{\Lambda} \) in Fig. 6(c) or \( K^0_S \) in Fig. 6(d), although, within the statistical errors, similar trends are seen for both identified particles. The overall systematic errors are on the order of 15% in the \( p_T \) region studied. The subevent method, however, introduced an additional factor described in Sec. II C 2 that leads to the enhanced ratio for both \( \Lambda + \bar{\Lambda} \) and \( K^0_S \). This opposite effect is also within the order of 15%.

To obtain good statistics, the event plane method is used for most analyses of identified particles. Depending on the analysis method, systematic uncertainties from variations in particle identification cuts, background subtractions, and summing of centrality bins are also estimated. By varying particle identification (PID) cuts, which change signal over background ratios by a factor of 3, the systematic uncertainty from the PID cuts is estimated to be about 5% below 4 \( \text{GeV}/c \). From 4 to 6 \( \text{GeV}/c \), this effect is larger in central collisions than peripheral collisions; and in the 0–10% bin, it is about a 10% effect. To estimate the uncertainty from background subtractions, background variations from different second- and fourth-order polynomial fit functions in Fig. 1 were propagated to measured \( v_2 \) values with Eq. (1). The effect is less than 3%. When combining centralities, the combined \( v_2 \) value should...
be a yield-weighted average of $v_2$ values in small centrality bins. In the method used previously [2], $v_2$ values are taken as weighted observed $v_2$ corrected by weighted event plane resolution. With the $v_2$ versus $m_{inv}$ method, similar corrections were calculated. They are less than 5% below 6 GeV/$c$.

In summary, for charged particles, a 15% difference for $(v_2)$ at midrapidity for 10–40% collisions between the event plane and the Lee-Yang zero methods has been observed. The difference between $v_2$ (EP) and $v_2$ (4) is smaller, $\sim$10%; but for the more peripheral and more central collisions, it seems to be closer to 20%. For $v_2(p_T)$ of $K^0_S$, and $\Lambda$, a difference also is observed between the event plane and the Lee-Yang zero methods. However, the comparison with charged particles shows that within the much larger statistical uncertainties for the $\Lambda$ and $K^0_S$ analysis, the different magnitudes of the estimated flow from the different methods observed are similar for charged particles and for the $\Lambda$ and $K^0_S$ particles. The uncertainty used is 15%. In a later section, the results are presented for $\Xi^-$ and the $\Omega^-$. For these particles, due to limited statistics, only the event plane method has been used, and therefore no real estimate of the systematic error is available. Instead, what was done, was to show the estimated systematic uncertainties obtained for the charged particles, taking into account effects from background estimation, summing centralities, and variations in cuts. A summary of our best knowledge of systematic errors is given in Table I.

### IV. DISCUSSION

#### A. Charged hadrons

Figure 5 shows that for the Lee-Yang zero method, the sum and product generating functions agree, but they are slightly lower than the four-particle cumulant method. The event plane method appears to be about 15% higher than the other methods. This could be due to either nonflow contributions increasing the event plane results or fluctuations of $v_2$ decreasing the multiparticle methods [8]. Charged hadron results give an indication of the systematic uncertainty inherent in the event plane method, which is used for most of the identified particles in this paper in order to reduce statistical errors. The $p_T$ dependence of this effect can be seen in Fig. 4. Note that the mentioned 15% nonflow effect is extracted only from the 10–40% centrality window. In other centrality bins, the effect may be larger. It should be possible to study this effect as a function of $p_T$ for all centralities with a future higher statistics data sample.

### B. Identified hadrons

The results for $\pi^+ + \pi^-$, $p + p$, $K^0_S$, $\Lambda + \bar{\Lambda}$, $\Xi^- + \Xi^+$, and $\Omega^- + \Omega^+$ are shown in Fig. 7 for various centralities of Au+Au collisions at 200 GeV. Shown are results for minimum bias and three other centrality bins. All $v_2(p_T)$ results are from the event plane method. The systematic uncertainties extracted from PID cuts, background subtractions, and combining centralities are shown as shaded bars in the figure. The systematic uncertainty in the method itself is not included. The shaded band in Fig. 7(c) indicates the systematic uncertainties for $K^0_S$ and $\Lambda$ for the 10–40% centrality bin, as discussed in the previous section. The results from an ideal hydrodynamic model [36,37] are displayed by the lines.

Figure 7 shows that the ideal hydrodynamic model calculations reproduce the mass ordering of $v_2$ in the relatively low $p_T$ region (the heavier the mass, the smaller the $v_2$), but overshoot the values of $v_2$ for all centrality bins. There seems to be a $p_T$ dependence in the disagreement, and for more central collisions, the overshoot does not take place until a higher $p_T$. In other words, the system agrees better with the ideal hydrodynamic model for more central collisions. Although we do not expect a large nonflow contribution at the low transverse momentum region, the centrality selections between the model calculations based on the impact parameter and the data based on the multiplicity are different, which may affect the model and data agreement. Note that we observe possible negative values of $v_2(p_T)$ for the heavier hadrons at the lowest observed $p_T$ in the most central Au+Au collisions.

At higher $p_T$, the hydrodynamic type mass ordering evolves into a hadron type ordering (baryons versus mesons). There the results show two groups depending on the number of quarks in the hadron; the baryons are higher than the mesons. The effects are clearly shown in Figs. 7(a), 7(b), and 7(c). However, in the most central bin [Fig. 7(d)], the effect is less pronounced. For all $p_T$, $v_2$ evolves toward larger values in going from central collisions to more peripheral collisions. The ideal hydrodynamic model also predicts this centrality dependence, though it fails to describe the behavior at higher $p_T$.

Figure 8 shows the same results as in Fig. 7 but as a function of the transverse kinetic energy $K_T = m_T - m = \sqrt{p_T^2 + m^2} - m$. Here $m$ is the particle mass. In this case, $v_2$ for all hadrons at low $K_T$ follow a universal curve, which appears to be monotonically increasing and almost linear in all centrality bins. The observed increase is slowest for the most central 0–10% bin. The corresponding results from the ideal hydrodynamic model calculations are also shown in the figure. The mass ordering in the model calculation is reversed when one plots $v_2$ versus $m_T - m$: the higher the mass the larger the value of $v_2$. While the data seem to show a scaling in the low $m_T - m$ region, the model results do not show any scaling.

In Figs. 9–11 we discuss the properties of the centrality dependence of the observed scaling including both the low $p_T \leq 2$ GeV/$c$ and the intermediate $2 \leq p_T \leq 5$ GeV/$c$ regions. Figure 9 shows $v_2$ scaled by the number of constituent quarks, $v_2/n_q$, for all strange hadrons including the pure multistrange hadrons $\phi$ and $\Omega$. The left panels show the results as a function of $p_T$ scaled by the number of quarks, $p_T/n_q$, and the right panels as a function of $K_T/n_q$. Figures 9(a) and
9(b) are the corresponding scaled results. It appears that the scaling works better when the data are plotted as a function of transverse kinetic energy $K_T$, as in Fig. 9(b). The ideal hydrodynamic results are also shown in both presentations. Clearly, the hydrodynamic distributions are also better scaled when plotted versus $K_T$. Polynomial fits were made for all hadrons. The results are shown as dot-dot-dashed lines in Figs. 9(a) and 9(b). The ratios of the data and the hydrodynamic lines over the polynomial fit are shown in Figs. 9(c) and 9(d). For all data, there is scaling at $p_T/n_q \geq 0.7$ GeV/c or $K_T/n_q \geq 0.2$ GeV/$c^2$. The errors from the multistrange hadrons $\phi$ [16] and $\Omega$ are large, see Figs. 9(e) and 9(f), but are consistent with the scaling. This observed $n_q$-scaling provides strong evidence that these hadrons are formed via a coalescence process at the end of the partonic evolution [11,13]. Compared with the light nonstrange hadrons, strange hadrons participate much less in later stage hadronic rescattering.

FIG. 7. (Color online) $v_2$ of $K^0_S$ (open circles), $\Lambda$ (open squares), $\Xi$ (filled triangles), and $\Omega$ (filled circles) as a function of $p_T$ for (a) 0–80%, (b) 40–80%, (c) 10–40%, and (d) 0–10% in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The error bars represent statistical uncertainties. The bands on the data points represent systematic uncertainties as discussed in the text. For comparison, pion (stars) and proton (filled squares) results are shown in (a). The systematic uncertainty of nonflow for $K^0_S$ and $\Lambda$ for 10–40% (c) is plotted as a shaded band near 0. For comparison, results from ideal hydrodynamic calculations [36,37] are shown: at a given $p_T$, from top to bottom, the lines represent the results for $\pi$, $K$, $p$, $\Lambda$, $\Xi$, and $\Omega$.

FIG. 8. (Color online) Same as Fig. 7, but as a function of $m_T - m$.

FIG. 9. (Color online) Number-of-quark scaled $v_2(v_2/n_q)$ of identified particles vs $p_T/n_q$ in (GeV/c) (left column) and $(m_T - m)/n_q$ in (GeV/$c^2$) (right column). Dot-dot-dashed lines are the results of sixth-order polynomial fits to $K^0_S$, $\Lambda$, $\Xi$, and $\Omega$. The ratios of the data points over the fit are shown in panels (c) and (d) for $K^0_S$, $\pi$, $p$, $\Lambda$, and $\Xi$, and in panels (e) and (f) for $\Omega$ and $\phi$ [16]. The error bars are shown only for the statistical uncertainties. Ideal hydrodynamic calculations for $\pi$, $K$, $\Lambda$, $\Xi$, and $\Omega$ are presented by solid lines, dashed lines, dot-dashed lines, dot-long-dashed lines, and dot-dot-dot-dashed lines, respectively. The ratio of hydrodynamic calculations over the fit are also shown for comparison in panels (c) and (d). The data are from minimum bias (0–80%) Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV.
scaling properties and the ratios, respectively. Similar to the universal scaling in Ref. [41] is not supported by the data. To further clarify the issue, instead of dividing the measured \( v_2 \) by the corresponding eccentricity \( \varepsilon_{\text{part}} \), we plot \( v_2(m_T - m)/n_q(v_2) \) for \( K^0_\Lambda, \Lambda, \Xi \) and \( \Omega \) in Fig. 12(c). The values of \( \langle v_2 \rangle \) (see Table III) are obtained by averaging \( v_2 \) as a function of transverse momentum weighted with the measured spectra. As one can see in the figure, for a given hadron, this scaling seems to work better. However, different hadrons seem to have different values of \( v_2 \), especially for the top 10% centrality bin at the higher \( m_T \).

Figure 12(d) shows the doubly scaled \( v_2 \) again. But this time, the integrated values of \( v_2 \) are extracted from the measurements of unidentified charged hadrons \( \langle v_2 \rangle_{\text{ch}} \) at the corresponding centrality bins. In this case, the scaling appears to work better. It is interesting to point out that at the most central bin, see inset in Fig. 12(d), the values of \( v_2 \) become negative at low \( p_T \) for all hadrons. This is most likely caused by the strong radial flow developed in central \( \text{Au}+\text{Au} \) collisions [42]. Similar behavior has also been observed in \( v_2 \) of \( \Lambda \) at SPS [43].

C. Universal scaling?

To analyze the centrality dependence of the scaling properties, we normalize the \( n_q \)-scaled elliptic flow \( v_2 \) by the participant eccentricity \( \varepsilon_{\text{part}} \) from a Monte Carlo Glauber calculation [39,40]. (See Table II for \( \varepsilon_{\text{part}} \).) The results are depicted in Fig. 12. Figures 12(a) and 12(b) show the doubly scaled quantities from three centrality bins as a function of \( p_T/n_q \) and \( (m_T - m)/n_q \), respectively. Both plots show an initial rise and a turn over to a flat region in the higher \( p_T \) region, and it is interesting to see that at a given centrality, the elliptic flow of all hadrons are scaled as observed in the minimum bias case (Fig. 9). After the geometric effect has been removed by dividing by \( \varepsilon_{\text{part}} \) in Figs. 12(a) and 12(b), the build up of stronger collective motion in more central collisions becomes obvious in the measured elliptic flow. This is consistent with the ideal hydrodynamic model calculations, shown as lines in Fig. 12(b), although the model results are much closer together. However, clearly there is no scaling among different collision centralities. Neither our data nor the model results indicate universal scaling with eccentricity. A careful inspection of the results presented in Ref. [41] shows there is no disagreement between data; rather, the statement of the universal scaling in Ref. [41] is not supported by the data.

To further clarify the issue, instead of dividing the measured \( v_2 \) by the corresponding eccentricity \( \varepsilon_{\text{part}} \), we plot \( v_2(m_T - m)/n_q(v_2) \) for \( K^0_\Lambda, \Lambda, \Xi \) and \( \Omega \) in Fig. 12(c). The values of \( \langle v_2 \rangle \) (see Table III) are obtained by averaging \( v_2 \) as a function of transverse momentum weighted with the measured spectra. As one can see in the figure, for a given hadron, this scaling seems to work better. However, different hadrons seem to have different values of \( v_2 \), especially for the top 10% centrality bin at the higher \( m_T \).

Figure 12(d) shows the doubly scaled \( v_2 \) again. But this time, the integrated values of \( v_2 \) are extracted from the measurements of unidentified charged hadrons \( \langle v_2 \rangle_{\text{ch}} \) at the corresponding centrality bins. In this case, the scaling appears to work better. It is interesting to point out that at the most central bin, see inset in Fig. 12(d), the values of \( v_2 \) become negative at low \( p_T \) for all hadrons. This is most likely caused by the strong radial flow developed in central \( \text{Au}+\text{Au} \) collisions [42]. Similar behavior has also been observed in \( v_2 \) of \( \Lambda \) at SPS [43].
D. Integrated $v_2/\epsilon_{\text{part}}$ vs collision centrality

The integrated elliptic flow values in Table III were obtained from the measured $v_2(p_T)$ and separately parametrized $p_T$ spectra. The $v_2(p_T)$ were integrated over $p_T$ weighted with the yield distribution from functions fitted to the spectra. To extend $v_2$ to low $p_T$, a sixth-order polynomial and an $n_g$-inspired function [44] were used to fit $v_2$. The $v_2$ values in the table are the average values from these two sets of parametrizations. The systematic uncertainties are taken as half of the differences between values from two sets of fits. The statistical errors as a function of $p_T$ are fitted with third-order polynomials and folded with the yield distributions into the errors of the integrated $v_2$. The spectra for $K^0_S$ and $\Lambda$ are from Ref. [45], and the spectra for $\Xi$ are from Ref. [14]. Data for $\phi$ mesons are from Ref. [16].

The centrality dependence of the ratio of the integrated elliptic flow (Table III) over the eccentricity ($v_2/\epsilon_{\text{part}}$) for charged hadrons, $K^0_S$, $\phi$ meson [16], $\Lambda$, and $\Xi$ are shown in Fig. 13. All these results are from the event plane method, and the number of participants is the average in the centrality bin. For comparison, results from an ideal hydrodynamic calculation [37,46] are also shown as dashed lines. This ratio to some extent reflects the strength of the collective expansion. At a more central collision, one would expect a stronger expansion, hence the larger value of the ratio. This is what one sees in Fig. 13 for charged hadrons. For identified hadrons, the increasing trend as a function of $N_{\text{part}}$ is there despite the large error bars. In the ideal hydrodynamic calculations [37,46], the first-order phase transition and freeze-out temperatures are set to be 165 and 130 MeV, respectively. With these parameters, the ideal hydrodynamic model results describe the pion, kaon, and proton transverse momentum spectra [37,46]. In a pure hydrodynamic model, one deals with energy-momentum cells rather than any specific type of hadrons, thus the initial condition, the equation of state and the freeze-out conditions used in the calculation are the same for all hadrons. Such assumptions may not be applicable to all hadrons, because some of them will continue to interact even after hydrodynamic freeze-out [47].

As expected in an equilibrium scenario, the model results show little sensitivity to the collision centrality. However, it is interesting to note that there is a clear hadron mass dependence of $v_2$ normalized by $\epsilon_{\text{part}}$ from the model calculations which is not seen in the data. It is not clear whether the mass dependence is from the collective motion at early time or is the effect of the hadronization process in the calculation. On the data side, the errors are too large to allow comparisons with model results. As one can see in Fig. 13, after $N_{\text{part}} \sim 170$, the measured ratios for the strange particles approach that from the ideal hydrodynamic model calculations. The consistency between model results and data indicates that the system created in 200 GeV Au+Au collisions may reach local thermalization in central collisions when the number of participants is larger than $\sim 170$. 

TABLE II. Participant eccentricity $\epsilon_{\text{part}}$, number of participants $N_{\text{part}}$, and number of binary collisions $N_{\text{bin}}$, from a Glauber calculation [39,40] for minimum bias and three other centrality bins. The errors are statistical from the calculations only. The $\epsilon_{\text{part}}$ values were not weighted with multiplicity when averaging over the centrality bin. The biggest systematic error is probably from the centrality binning based on the impact parameter compared to the binning of the data based on the multiplicity. All parameters for 62.4 GeV Au+Au collisions are calculated in a similar fashion as for 200 GeV collisions. The p+p cross sections used were 36 mb at 62.4 GeV and 42 mb at 200 GeV.

flow is expected from higher energy collisions [49]. In Fig. 14, the ratios for both $K_S^0$ and $\Lambda$ are similar. While the higher energy ratios show a decreasing trend as a function of $p_T$, the lower energy ratios seem to increase with transverse momentum. In the low $p_T$ region ($\leq 1.5$ GeV/c), the strength of flow is similar in 200 GeV and 62.4 GeV Au+Au collisions. For the 0–80% Au+Au collisions, the values of the participant eccentricity from 62.4 and 200 GeV are 0.392 and 0.384, respectively. The lack of energy dependence in $v_2$ for $K_S^0$ and $\Lambda$ is due to the similarity in the participant eccentricity. The PHOBOS experiment reported a similar observation for the $v_2$ of charged hadrons [50]. As discussed in Ref. [48], from 62 to 200 GeV, the participant-normalized charged hadron density at midrapidity increased by about 50%. However, we do not observe a change of a similar size in the participant eccentricity and $v_2$, indicating that a large fraction of the particle production occurs at the later stage of heavy ion collisions at these beam energies.

The ratio is less than unity in the low $p_T$ region [see Fig. 14(b)] indicating that the flow is weaker in the lower energy Pb+Pb collisions [43]. The collective velocity parameters, extracted from the transverse momentum spectra, are also found to be larger in 200 GeV Au+Au collisions than those from 17.2 GeV Pb+Pb collisions [11]. Since elliptic flow develops at a relatively early stage of the collision, the observed increase in collective flow in Au+Au collisions at RHIC is therefore caused by early partonic interactions [7–9].

**E. Energy dependence**

The transverse momentum dependence of eccentricity-scaled $v_2$ ratios are shown in Fig. 14(a) for data from 62.4 GeV (Au+Au collisions) and Fig. 14(b) for data from 17.2 GeV (Pb+Pb collisions [43]) over 200 GeV Au+Au collision data. It has been observed [48] that since the charged multiplicity production per participant is proportional to the square root of the e.m. energy [48], $dN/d\eta/(N_{\text{part}}/2) \propto \sqrt{s_{NN}}$, a stronger

**FIG. 13.** (Color online) Centrality dependence of $v_2/n_{\text{part}}$ vs number of participants for charged hadrons (crosses), $K_S^0$ (circles), $\phi$ (stars) [16], $\Lambda + \bar{\Lambda}$ (squares), and $\Xi + \bar{\Xi}$ (triangles). Both unidentified charged hadron and identified hadron $v_2$ were analyzed with the standard event plane method. All data are from $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions. The data points are displaced slightly horizontally for clarity. The statistical and systematic uncertainties are shown as bars and brackets, respectively. Ideal hydrodynamic model calculations are also shown as dashed lines [37,46] for, from top to bottom, $\Omega$, $\Xi$, $\Lambda$, $p$, $K$, and $\pi$.

**FIG. 12.** (Color online) $v_2$ scaled by the number of quarks $n_q$ and participant eccentricity $\varepsilon_{\text{part}} [v_2/(n_q \varepsilon_{\text{part}})]$ of identified particles (particle+antiparticle) vs (a) the scaled $p_T/n_q$ and (b) $(m_T - m)/n_q$ for three centrality bins. For comparison, ideal hydrodynamic model calculations are shown as lines in (b). In (c), data from (b) are scaled by the integrated $v_2$ of each particle, instead of $\varepsilon_{\text{part}}$. In (d), data from (b) are scaled by the integrated $v_2$ of all charged hadrons. The insert in (d) expands the low $m_T$ region. Error bars are shown only for statistical uncertainties. All data are from $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions.
Figure 14 shows the centrality dependence of $v_2$ normalized by the number of quarks and eccentricity $v_2/(n_q \Delta v)$ for identified hadrons from 62.4 [51] and 200 GeV Au+Au collisions. Within error bars, data from both energies are similar. At the low transverse energy region, the scaled $v_2$ shows almost a linear increase and then becomes flat. For more central collisions, the turning point is at higher values of $(m_T - m)/n_q$. Recently, PHENIX reported a charged hadron scaling with eccentricity, system size, and the transverse energy $(m_T - m)$ up to 1 GeV/$c^2$ [41]. As one can see from the figure, at a given centrality, independent of the collision energy, there is a clear scaling: all values of $v_2/(n_q \Delta v)$ coalesce into a single distribution. On the other hand, at different centralities, the shape of the distributions are different, meaning that there is no scaling in the measured $v_2$ with the eccentricity, especially in the higher transverse energy region.

V. SUMMARY

We present STAR results on the elliptic flow $v_2$ of unidentified charged hadrons and strange and multistrange hadrons from $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions at RHIC. The centrality dependence of $v_2$ over a broad transverse momentum range is presented. Comparison of different analysis methods are made in order to estimate systematic uncertainties. The rapidity dependence of the charged hadron $v_2$ from these measurements is consistent, at both midpseudorapidity and forward rapidities, with both STAR [8] and PHOBOS [35] reported results. In particular, the results for $v_2$ from the Lee-Yang zero method for charged hadrons, $K^0_S$, and $\Lambda$ are shown for the first time at RHIC. The nonflow effects, studied in the 10–40% centrality window, are on the order of 10% within 0.2 $< p_T < 3$ GeV/$c$ and up to 25% at $p_T \sim 6$ GeV/$c$.

In the relatively low $p_T$ region, $p_T < 2$ GeV/$c$, a scaling with $m_T - m$ is observed for identified hadrons under study in each centrality bin, and there is a clear centrality dependence in the scaling. However, we do not observe $v_2(m_T - m)$ scaled by the participant eccentricity to be independent of centrality. The largest values of the participant eccentricity scaled $v_2$ are in the most central collisions. For the most central collisions (0–10%), negative values of $v_2$ at the lowest $p_T$ studied have been observed for both $K^0_S$ and $\Lambda$. This is the first time a negative $v_2$ in Au+Au collisions at RHIC has been found. It is consistent with the strong expansion observed in hadron spectra analysis [11]. In the higher $p_T$ region, $2 < p_T < 6$ GeV/$c$, number-of-quark scaling is observed for all particles under study. For the multistrange hadron $\Omega$, which does not suffer appreciable hadronic interactions, the values of $v_2$ are consistent with both $m_T - m$ scaling at low $p_T$ and number-of-quark scaling at intermediate $p_T$.

As a function of collision centrality, an increase of $p_T$-integrated $v_2$ scaled by the participant eccentricity has been observed, indicating stronger collective flow in more central
Au+Au collisions. However, in the higher transverse energy region, there is no scaling of $v_2$ with eccentricity.

The energy dependence of $v_2$ for $K^0_S$ and $\Lambda$ was presented for $\sqrt{s_{NN}} = 17$ GeV Pb+Pb, and 62 and 200 GeV Au+Au collisions. No clear systematic trend was observed, but the differences were only on the order of 10%.

For comparison, results from ideal hydrodynamic model calculations were used. The calculations overpredict the data at $p_T \geq 2$ GeV/$c$. At low $p_T$, although the model predicts correctly the mass hierarchy observed in the data, there is no scaling with $m_T - m$, and no scaling with the number of quarks is observed throughout the $p_T$ region for all hadrons. We observe that the mass ordering at low $p_T$ alone is not sufficient to claim thermalization in Au+Au collisions at RHIC.

ACKNOWLEDGMENTS

We thank Jean-Yves Ollitrault and Nicolas Borghini for help in understanding the Lee-Yang zero method. We also thank the RHIC Operations Group and RCF at BNL, the NERSC Center at LBNL, and the Open Science Grid consortium for their support.
