Azimuthally anisotropic emission of low-momentum direct photons in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV
The PHENIX experiment at the BNL Relativistic Heavy Ion Collider has measured second- and third-order Fourier coefficients of the azimuthal distributions of direct photons emitted at midrapidity in $Au + Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV for various collision centralities. Combining two different analysis techniques, results were obtained in the transverse momentum range of $0.4 < p_T < 4.0$ GeV/$c$. At low $p_T$ the second-order coefficients, $v_2$, are similar to the ones observed in hadrons. Third-order coefficients, $v_3$, are nonzero and almost independent of centrality. These new results on $v_2$ and $v_3$, combined with previously published results on yields, are compared to model calculations that provide yields and asymmetries in the same framework. Those models are challenged to explain simultaneously the observed large yield and large azimuthal anisotropies.

DOI: 10.1103/PhysRevC.94.064901

I. INTRODUCTION

Direct photons emerging from relativistic heavy-ion collisions have long been considered an important probe of the entire evolution of the colliding system [1]. At almost all known or conjectured stages of the collision there are processes producing photons. Unlike hadronic observables that mostly encode the state of the medium at freeze-out, photons are emitted at all times throughout the rapid evolution of the heavy-ion collision and leave the interaction region unmodified. Thus by measuring direct photons one has access to information about the properties and dynamics of the medium integrated over space and time. The measurement of direct photons is challenging due to a large background of photons from the vacuum decay of final state hadrons ($\pi^0$, $\eta$, $\omega$, etc.).
The PHENIX experiment at the BNL Relativistic Heavy Ion Collider reported large direct photon yields [2] with strong centrality dependence [3] and significant azimuthal anisotropy or “elliptic flow” [4]. Particularly surprising is the discovery of large azimuthal anisotropy for direct photons [4], which is comparable to that observed for hadrons [5]. Preliminary results from the CERN Large Hadron Collider [6,7] indicate similar direct photon yields and anisotropies. The observation of large azimuthal anisotropy combined with observations published earlier that the direct photon yields themselves are large [2,3] contradicts several existing interpretations where the large yields are provided at the very early production stage, when the temperature of the system is highest but the collective flow including azimuthal asymmetry is negligible. Conversely, the observed large anisotropy suggests that photon production occurs at very late stages of the collision when the collective flow of the system is fully developed, while the temperature and the corresponding thermal emission rates are already lower. Indeed, theoretical models have great difficulty to simultaneously describe the observed yields and anisotropy. This failure, colloquially called “the direct photon puzzle,” triggered a large amount of theoretical work, new models, and insights [8–31].

In this article we present new, more precise results on the azimuthal anisotropy of direct photon emission from 200-GeV Au + Au collisions recorded in 2007 and 2010 by the PHENIX experiment. Results include second- and third-order Fourier components of azimuthal distributions (v2 and v3, respectively) measured over a transverse momentum range extended down to 0.4 GeV/c. The new data, together with published results on yields, are compared to some of the more recent model calculations.

The article is organized as follows. In Sec. II we describe the experiment, the data set, the way events are selected and categorized, and the two methods by which photons are measured. In Sec. III the steps needed to determine the direct photon v2 and v3 and their uncertainties are described, and the final results are presented. In Sec. IV the results are compared to a few models treating yields and azimuthal asymmetries in a consistent framework. Section V summarizes our findings.

II. EXPERIMENTAL SETUP AND PHOTON MEASUREMENTS

In the PHENIX experiment photons are detected by two substantially different techniques. The first technique uses external conversion of photons as described in detail in Ref. [3]. This method provides a high-purity photon sample with good momentum resolution, but requires large statistics due to the few percent conversion probability and reduced acceptance. Therefore the \( p_T \) range is limited. The second technique is a traditional calorimetric measurement of photons similar to Ref. [4], but with higher statistics. For photons identified by either technique, the azimuthal anisotropy is extracted with the event plane (EP) method. Here we give a brief summary of the PHENIX detector systems and a short description of the two analyses.

A. Event selection and centrality determination

Data from 200-GeV Au + Au collisions were recorded with a minimum-bias (MB) trigger based on the signal in the beam-beam counters (BBCs) [32], which are located around the beampipe at 3.1 < \( |\eta| \) < 3.9 and cover the full azimuth. The MB trigger requires at least two hits in each of the two BBCs (north and south) as well as a reconstructed vertex from the time-of-flight difference between the two sides. The efficiency of the MB trigger is 92.3 ± 0.4(stat) ± 1.6(sys)%.

Collision centrality is calculated as percentiles of the total charge distribution in the north and south BBCs. The centrality determination is based on percentiles of the total charge seen in the north and south BBCs and takes into account small shifts in \( \eta \) coverage due to variations of the collision’s \( z \) vertex.

B. Inclusive photons via external conversion

External conversion photons are reconstructed from \( \sqrt{s_{NN}} = 200 \) GeV Au + Au events recorded during the 2010 data taking period. The event vertex in this data set was \( |z| < 10 \) cm to ensure that the magnetic field would be sufficiently uniform. The same sample was previously used in Ref. [3] to determine direct photon yield and its centrality dependence, where details of this analysis can be found. In the rest of this article this sample is referred to as “conversion photons.”

Photons convert to \( e^+e^- \) pairs in the readout plane of the hadron blind detector (HBD) [33], which is located at \( \sim 60 \) cm radial distance from the collision vertex and corresponds to \( \sim 3\% \) \( X_0 \), where \( X_0 \) is the radiation length. The electron and positron from the photon conversion are tracked through the PHENIX central tracking detectors [34]. The azimuthal direction \( \phi \) and the momentum \( p \) are reconstructed from the drift-chamber information, while the polar angle of each track is determined by a point measurement in the innermost pad-chamber and the collision vertex. High-efficiency electron identification cuts are used to reduce the hadron contamination in the sample. Light above a minimum threshold in the ring-imaging Čerenkov detector [35] and a matching cluster of energy \( E \) in the electromagnetic calorimeter (EMCal) [36] such that \( E > 0.15 \) GeV and \( E/p > 0.5 \), where \( p \) is the momentum, are required. The EMCal comprises two calorimeter types: six sectors of lead scintillator sampling calorimeter (PbSc) and two sectors of lead glass Čerenkov calorimeter (PbGl). The typical energy resolution of the PbSc is \( \delta E/E = 8.1%/\sqrt{E(\text{GeV})} \pm 2.1\% \), and that of the PbGl is \( \delta E/E = 5.9%/\sqrt{E(\text{GeV})} \pm 0.8\% \). The energy resolution, just like the photon identification efficiency, depends on centrality and its (small) effect is corrected for using simulated photon showers embedded into real events.

All remaining tracks with \( p_T > 0.2 \) GeV/c, are combined into pairs. Conversion photons are identified by analyzing the invariant mass of the pairs. The default tracking in PHENIX assumes that each track originates at the collision vertex. Thus, if the \( e^+e^- \) pair comes from a conversion of a real photon in the HBD readout plane, the momenta will be mismeasured and a finite mass, in this case about \( m_{ee} \sim 12 \) MeV/c\(^2\), will be reconstructed. Conversely, if the momenta are recalculated assuming the HBD readout plane as the origin, the invariant
mass is close to zero. Through a simultaneous cut on both mass calculations a sample of photon conversions with a purity of 99% is obtained down to $p_T = 0.4$ GeV/c [3]. The remaining 1% of pairs are mostly from the $\pi^0$ Dalitz decays. The effect on the inclusive photon $v_2$ is estimated to be smaller than 1%.

C. Inclusive photons and $\pi^0$s via the calorimeter

The PHENIX EMCal is the principal detector in the calorimetric analysis, which is performed in a similar way as in Ref. [4]. The $v_2$ and $v_3$ are measured simultaneously for inclusive photons and $\pi^0$s. A total of $4.4 \times 10^9$ MB Au + Au events from the 2007 data-taking period are analyzed. The event vertex in this sample was $|z| < 30$ cm.

Photon candidates in the EMCal are clusters above a threshold energy of 0.2 GeV that pass a shower shape cut as well as a charged particle veto cut by the pad chamber PC3 immediately in front of the EMCal. However, photon candidates with less than 1 GeV energy are only used to reconstruct $\pi^0$, but are not included in the inclusive photon sample of the calorimeter. As described in Ref. [37], the remaining hadron contamination was estimated by comparing GEANT simulations, verified with actual data. The $\pi^0$ is measured via the $2\gamma$ decay channel, with a cut on the energy asymmetry of the two photons $\alpha = \frac{|E_1 - E_2|}{E_1 + E_2} < 0.8$. For each $p_T$ bin the number of reconstructed $\pi^0$s is taken as the integral of the two-photon invariant mass distribution, with the combinatorial background subtracted by the mixed event method [38]. The signal to background ratio at $1.0 < p_T < 1.5$ GeV/c is $0.1$, rapidly improving with increasing $p_T$.

For the inclusive photon measurement it is important to restrict the measurement to a region where the residual contamination from misidentified hadrons is small. Therefore, in the inclusive photon sample only clusters with $E > 1$ GeV are considered. On the other hand the inclusive (and direct) photon results presented here have an upper range of 4 GeV/c, which is far from the threshold where two decay photons from a $\pi^0$ can merge in the calorimeter. Within this $p_T$ range a purity of larger than 95% is achieved. The largest contamination of the photon sample results from antineutrons, which are not removed by the charge particle veto but deposit significant energy through annihilation. The systematic uncertainty from particle identification of photons is estimated by varying both the shower shape cut (five different settings) and, independently, by applying or omitting the charged particle veto cut. Results from all cut variations are then fully corrected. The deviation between results is 3%–4%, which is quoted as systematic uncertainty on the inclusive photon yield.

D. Event plane determination

PHENIX has different detector systems to establish the determination of the event plane, note that they are separated as in Ref. [4]. The calorimetric analysis, which is performed in a similar way <outer and inner reaction plane detector (RxNO, 1 < |$\eta$| < 1.5, RxNI, 1.5 < |$\eta$| < 2.8), the muon piston calorimeters (MPCS, −3.7 < $\eta$ < 3.1, MPCN, 3.1 < $\eta$ < 3.9), and the BBC (3.1 < |$\eta$| < 3.9)). All these detectors cover the full $2\pi$ azimuth and are sufficiently separated in $\eta$ such that we do not expect autocorrelations between the event plane determination and the production asymmetry measured. The RxNI and RXNO are scintillation counter systems with a 2-cm Pb converter that makes them sensitive to photons in addition to charged particles. While these photons contribute to the determination of the event plane, note that they are separated at least $\Delta \eta = 0.7$ from the central region, which is where the photon $v_2$ and $v_3$ are measured.

The results in this article are obtained using the event planes measured by the combination of the RxNI and the RxNO [39]. Due to the large rapidity coverage this combination has the best resolution. The resolution $\text{Res}(\Psi_{kn})$ is measured with the two-subevent method [40]. The resolution for the RxN and MPC detectors is shown in Fig. 1. The final results are cross-checked by using the other detectors for the event plane determination. Despite the significant difference in resolution the measured direct photon anisotropies are consistent, within the systematic uncertainties.

III. DIRECT PHOTON $v_2$ AND $v_3$

The photon anisotropy is measured via the coefficients of a Fourier decomposition of the azimuthal distributions of photons with respect to the event plane [40]:

$$\frac{dN}{d(\phi - \Psi_k)} \propto 1 + \sum_n \{v_{kn} \cos [n(\phi - \Psi_k)]\},$$

where $\phi$ is the azimuthal angle of the photon, $\Psi_k$ is the orientation of the $k^{th}$ event plane for a given event, and $v_{kn}$ are the $n^{th}$ coefficients with respect to the $k^{th}$ event plane. In our analysis we made and explicitly tested the assumption that the second- and third-order event planes are uncorrelated, which allows us to ignore the $k \neq n$ terms and to introduce the notation $v_2$ and $v_3$ for the case $k = n$; i.e., in the rest of the article we use $v_2 \equiv v_{22}$ and $v_3 \equiv v_{33}$.

The determination of the direct photon $v_2$ and $v_3$ proceeds in three steps: (i) $v_2$ and $v_3$ are determined for the conversion photon sample (Sec. II B) and for the calorimeter photon sample (Sec. II C) with respect to the event plane (Sec. II D). We refer to these coefficients as inclusive photon $v_2^{inc}$ and
The inclusive photon $v_2$ and $v_3$ are measured with respect to the event plane. We employ two methods to determine these coefficients. For each photon the azimuthal angular difference ($\phi - \Psi_k$), with $k = 2$ and 3, is calculated. In the first method the coefficients are determined as the event ensemble average for individual bins in photon $p_T$ and centrality:

$$v_n = \cos \{n(\phi - \Psi_n)\}/\text{Res}(\Psi_n).$$

(2)

Here $\text{Res}(\Psi_n)$ is the resolution function that accounts for the finite event plane resolution (see Fig. 1).

In the second method the azimuthal distribution of photons in a given $p_T$ and centrality bin is fitted as

$$\frac{dN}{d(\phi - \Psi_n)} = N_0[1 + 2v'_n \cos \{n(\phi - \Psi_n)\}],$$

(3)

$$v_n = v'_n/\text{Res}(\Psi_n).$$

(4)

This is Eq. (1) for the case $k = n$ and neglecting all $k \neq n$ terms. The measured values of $v_2$ and $v_3 (v'_2, v'_3)$ need to be corrected for the event plane resolution.

In the conversion photon method the quoted $v_n$ values come from the average cosine method, while in the calorimeter analysis the quoted $v_n$ values are the average of the results obtained with the two methods. The difference between the two methods is less than 1%. The results for the inclusive photon $v_2$ and $v_3$ are shown in Fig. 2. Both measurements agree in the region where they overlap.

### A. Inclusive photon $v_2$ and $v_3$

The inclusive photon $v_2$ and $v_3$ are measured with respect to the event plane. We employ two methods to determine these coefficients. For each photon the azimuthal angular difference ($\phi - \Psi_k$), with $k = 2$ and 3, is calculated. In the first method the coefficients are determined as the event ensemble average for individual bins in photon $p_T$ and centrality:

$$v_n = \cos \{n(\phi - \Psi_n)\}/\text{Res}(\Psi_n).$$

(2)

Here $\text{Res}(\Psi_n)$ is the resolution function that accounts for the finite event plane resolution (see Fig. 1).

In the second method the azimuthal distribution of photons in a given $p_T$ and centrality bin is fitted as

$$\frac{dN}{d(\phi - \Psi_n)} = N_0[1 + 2v'_n \cos \{n(\phi - \Psi_n)\}],$$

(3)

$$v_n = v'_n/\text{Res}(\Psi_n).$$

(4)

This is Eq. (1) for the case $k = n$ and neglecting all $k \neq n$ terms. The measured values of $v_2$ and $v_3 (v'_2, v'_3)$ need to be corrected for the event plane resolution.

In the conversion photon method the quoted $v_n$ values come from the average cosine method, while in the calorimeter analysis the quoted $v_n$ values are the average of the results obtained with the two methods. The difference between the two methods is less than 1%. The results for the inclusive photon $v_2$ and $v_3$ are shown in Fig. 2. Both measurements agree in the region where they overlap.

### B. Decay photon $v_2$ and $v_3$

About 80%–90% of the inclusive photons come from decays of neutral mesons and exhibit an anisotropy with respect to the event plane that results from the anisotropy of the parent mesons [4]. To estimate this contribution we use measured yields and anisotropy for charged and neutral pions; $v_n$ for heavier mesons is obtained by $K_{ET}$ scaling as described below. The yields of mesons used here are the same as those used for the measurement of $R_g$ in Ref. [3].

The $v_2$ and $v_3$ for pions are determined by combining data from different measurements of charged and neutral pion $v_2$ and $v_3$. The $\pi^0 v_2$ has been published in Ref. [41] but the measurement has been repeated in this analysis to check the consistency of the results. The method to count the number of
\[ v_n^{\text{meson}}(KE_T) = v_n^\pi(KE_T), \]  
\[ KE_T = m_T - m = \sqrt{p_T^2 + m^2} - m, \]

where \( m \) is the mass of the corresponding meson.

The yields of the heavier mesons are determined from the \( \pi^0 \) yields at \( p_T = 5 \) GeV/c using the following ratios: \( \eta/\pi^0 = 0.46 \pm 0.060, \omega/\pi^0 = 0.83 \pm 0.12, \rho/\pi^0 = 1.00 \pm 0.300, \) and \( \eta'/\pi^0 = 0.25 \pm 0.075. \)

Below \( p_T = 2 \) GeV/c \( KET \) scaling is only an extrapolation for the \( \eta \) yields. Therefore, we also applied a blast-wave fit, and the difference is included in the systematic uncertainties. Note that the blast-wave fit results in a lower \( \eta \) yield at small \( p_T \), increasing the direct photon yield and its \( v_2 \) and \( v_3 \). The meson yields, momentum spectra, and \( v_n \) are used to simulate mesons that are then decayed to all decay chains including photons. From the simulation we calculate the decay photon \( v_n^{\text{dec}} \) using Eq. (2) with \( \text{Res}(\Psi_n) = 1 \), because the event plane is known in the simulation. The only source of systematic uncertainty on \( v_n^{\text{dec}} \) is the uncertainty of the measured \( \pi^0 \) \( v_2 \) and \( v_3 \), and the resulting decay photon \( v_2 \) and \( v_3 \), derived from it. The resulting \( v_n^{\text{inc}} \) is compared to the inclusive photon \( v_n \) in Fig. 2. We find that the decay photon \( v_n \) and the inclusive photon \( v_n^{\text{inc}} \) are similar. This was already observed for \( v_2 \) in Ref. [4], but is now also found for \( v_3 \). Given that a finite direct photon yield has already been established [2,3], the similarity of \( v_n^{\text{inc}} \) and \( v_n^{\text{inc}} \) implies a large direct photon \( v_3 \), as is shown in the next section.

C. Direct photon \( v_2 \) and \( v_3 \)

The \( v_2 \) and \( v_3 \) for direct photons are extracted from the measured inclusive photon \( v_n^{\text{inc}} \), the decay photon \( v_n^{\text{dec}} \), discussed in the previous sections, and the ratio of the inclusive to decay photon yield \( R_y \) measured in Ref. [3]. The procedure was introduced in Ref. [4]:

\[ v_n^{\text{dir}} = \frac{R_y v_n^{\text{inc}} - v_n^{\text{dec}}}{R_y - 1}. \]

We reproduce \( R_y \) from Ref. [3] with statistical and systematic uncertainties in Fig. 4.

All systematic uncertainties on the individual contributions on \( v_n^{\text{dir}} \) are summarized in Table I. Uncertainties that are uncorrelated between data points are called Type A, those that are correlated are Type B, and uncertainties that change all points by a common multiplicative factor are called Type C. Uncertainties on \( R_y \) are common for \( v_2 \) and \( v_3 \) and for the conversion and calorimeter methods. For photon and pion \( v_n \) measurements with PHENIX, the orientation of the event planes, i.e., \( \Psi_n \), is determined with the same detectors using the same algorithms. Thus the systematic uncertainty on the event plane determination is common for all \( v_2 \) (\( v_3 \)) measurements. The uncertainties on the decay photon \( v_n \) are common to the conversion and calorimeter methods. The systematic uncertainty on \( v_n^{\text{inc}} \) is independent

The averaged values used in our analysis are shown as a thick solid line together with the estimated statistical (dotted line) and systematic (light solid line) uncertainties. Bottom panels: Ratio of the measured \( v_2 \) (b) and \( v_3 \) (d) values to the averaged values.
for the two methods and mostly reflects the different purity of >95% compared to >99% for the calorimeter and conversion methods, respectively.

TABLE I. Summary of systematic uncertainties on the input to the measurement of \( v_n^{\text{dir}} \), where the \( R_y \) is from Ref. [3] and the \( v_n^{\text{inc}} \) and \( v_n^{\text{dec}} \) indicate “inclusive” and “decay” photons, respectively. The values are quoted for \( p_T < 3 \text{ GeV}/c \), although most do not vary with \( p_T \), as can be seen from Figs. 2 and 3. The uncertainties on the \( v_n^{\text{dec}} \) due to the statistical uncertainty of the input data are uncorrelated between data points (type A); they are included in the statistical errors on the final results. Type B uncertainties are correlated in \( p_T \); i.e., they can vary with \( p_T \) but only smoothly in the quoted range. Type C uncertainties change \( v_n^{\text{dir}} \) for all \( p_T \) by a constant multiplicative factor. The systematic uncertainties on \( v_2 \) and \( v_3 \) are typical values.

FIG. 4. The inclusive over decay photon ratio \( R_y \) used in the current analysis. Present data means the results published in Ref. [3].

FIG. 5. This example shows the direct photon \( v_n^{\text{dir}} \) measured via the calorimeter method with the event plane estimated by the reaction plane detector (1 < \( |\eta| < 2.8 \)) in the 0%–20% centrality bin. Each of the various dashed curves indicate the probability distribution of the \( v_n^{\text{dir}} \) result due to the variation of a single term in Eq. (7). While varying \( v_n^{\text{inc}} \) and \( v_n^{\text{dec}} \) alone leaves the uncertainty on \( v_n^{\text{dir}} \) Gaussian, varying \( R_y \) results in strongly asymmetric shapes. The black solid curve shows the result when all uncertainties are taken into account simultaneously.

Using Gaussian error propagation, the statistical and systematic uncertainties would be calculated as

\[
\sigma_{\text{\( v_n^{\text{dir}} \)}}^2 = \left( \frac{R_y}{R_y - 1} \right)^2 \sigma_{\text{\( v_n^{\text{inc}} \)}}^2 + \left( \frac{1}{R_y - 1} \right)^2 \sigma_{\text{\( v_n^{\text{dec}} \)}}^2 + \frac{1}{2} \left( \frac{\sigma_{\text{\( v_n^{\text{inc}} \)}}^2 + \sigma_{\text{\( v_n^{\text{dec}} \)}}^2}{R_y - 1} \right) \sigma_{\text{\( R_y \)}}^2.
\]

Except for the case \( v_n^{\text{inc}} = v_n^{\text{dec}} \), there is a nonlinear dependence on \( R_y \) that, combined with uncertainties of 20%–30% on \( (R_y - 1) \), results in asymmetric uncertainties, which are not described by Eq. (8). In particular, for the case \( v_n^{\text{inc}} > v_n^{\text{dec}} \), the uncertainties on \( v_n^{\text{inc}} \) and \( v_n^{\text{dec}} \) are amplified if \( R_y \) is small.

We estimate these asymmetric uncertainties by modeling a probability distribution for possible values of \( v_n^{\text{dir}} \) using the statistical and systematic uncertainties on \( v_n^{\text{inc}}, v_n^{\text{dec}}, R_y \), and the event plane resolution. We assume that the individual statistical and systematic uncertainties follow Gaussian probability distributions. The probability distribution for \( v_n^{\text{dir}} \) is then determined by generating many combinations of \( v_n^{\text{inc}}, v_n^{\text{dec}}, \) and \( R_y \). Figure 5 shows one example of a probability distribution based on the systematic uncertainties on the calorimeter measurement for 0%–20% centrality and \( 1 < p_T < 1.5 \text{ GeV}/c \). In Fig. 5 the effect of the uncertainty of only \( v_n^{\text{inc}}, v_n^{\text{dec}}, \) or \( R_y \), are plotted separately. The asymmetry due to the uncertainty of \( R_y \) is clearly visible.

Probability distributions based on statistical (including type A systematics) and systematic uncertainties are determined for each \( v_n^{\text{dir}} \) data point in \( p_T \) and centrality and for both analyses. The central value for each data point was calculated using Eq. (7). We note that the peak or median of the probability distributions used to determine the statistical and systematic
uncertainties agrees with the calculated central value to better than the symbol size. From each distribution we calculate the lower and upper bounds on the uncertainty by integrating from $\pm \infty$ to a $v_n$ for which the integrated probability reaches 15.9%. These values bracket a 68% probability range for $v_n$ and are quoted as upper and lower statistical and systematic uncertainties on the final result.

The final results for the direct photon $v_2$ and $v_3$, including statistical and systematic uncertainties as outlined above, are shown in Fig. 6 for three centralities and separately for the two analysis methods. For the conversion method $v_3$ is shown only for the highest centrality bin; the statistical fluctuations preclude any meaningful measurement in the more peripheral bins. The data and their uncertainties are shown in Tables II and III.

The two analysis techniques are very different but the results agree well in the overlap region, and they are also consistent with the results published earlier [4]. The direct photon $v_2$ centrality dependence, both in trend and magnitude, is quite similar to the observed pion $v_2$. The third-order coefficients $v_3$ are consistent with no centrality dependence.

### IV. COMPARISONS TO MODELS

As already mentioned, the essence of the “direct photon puzzle” is that current theoretical scenarios have difficulties explaining the large direct photon yield and azimuthal asymmetries at the same time. This is illustrated by a recent state-of-the-art calculation of viscous hydrodynamic calculation of photon emission with fluctuating initial density profiles and standard thermal rates [17], which falls significantly short in describing yield and $v_2$. Over the past few years many new ideas have been proposed to resolve this puzzle, including nonequilibrium effects [19,24,26,28], enhanced early emission due to large magnetic fields [15,25,27], enhanced emission at hadronization [31], and modifications of the formation time and initial conditions [20,22,23].

In this subsection we compare our results to a subset of the models which (i) consider thermal radiation from the quark-gluon plasma (QGP) and HG (hadron gas) plus additional proposed sources, (ii) have a complete model for the space-time evolution, and (iii) calculate absolute yields and $v_2$. For the comparison we use the data for the 20%–40% centrality class, and note that the comparison leads to similar conclusions for the other centrality bins. While none of the models describe all aspects of the available data, they are representative of how different theories are trying to cope with the challenge.

First, we compare the data to the “fireball” scenario originally calculated in Ref. [12]. The model includes perturbative quantum chromodynamics (pQCD), QGP, and HG contributions, with the instantaneous rates convoluted with a fireball expansion profile. The basic parameter is the initial transverse acceleration of the fireball, $a_T$. The prompt photon component is estimated in two ways. The first variant is a parametrization of the photon yields measured in $p + p$ by the PHENIX experiment [45] (labeled as “primordial 1”); the second is an $x_\gamma$-scaling motivated parametrization (labeled as “primordial 2”), modified with the empirical factor $K = 2.5$ to match the measured data at high $p_T$ (above 4 GeV/c). The yield calculation includes thermal yields from the QGP with $T_0 = 350$ MeV and from the hadronic phase. Different from an earlier version of the model, chemical equilibrium prior to kinetic freeze-out is no longer assumed. This results in a large enhancement in photon production in the later hadronic stages via processes like meson annihilation (for instance, $\pi + p \rightarrow \pi + \gamma$). With an initial transverse acceleration of $a_T = 0.12$ $c^2$/fm and $\tau \approx 15$ fm/$c$ fireball lifetime, 100 MeV freeze-out temperature, and $\beta_s = 0.77$ surface velocity, the observed

low-$p_T$ photon yields are recovered within systematic uncertainties, but underpredict the data [12]. In Fig. 7 the data are compared to the most recent updated “fireball” scenario shown in Ref. [18], which includes a calculation with ideal hydrodynamics with finite initial flow at thermalization and enhanced yields around the chemical freeze-out temperature $T_f$ that improves the description of the data. The direct photon $v_2$ has its maximum at about the same $p_T$ in both theory and

FIG. 7. Comparison of the direct photon yields [3] and $v_2$ with the fireball model [18]. The two curves for $v_2$ correspond to two different parametrizations of the prompt photon component. See text for details.

data. The $v_2$ calculated in the original fireball scenario [12] under predicts the measured one. The radial boost hardens the photons from the HG and in this way increases $v_2$ as well, but the calculation still falls short of the measurement. $v_3$ is currently not calculated in this model.

Second, in Fig. 8 the data are compared to three calculations evaluated with the hydrodynamical background as described in Refs. [46,47]. The first calculation, labeled “QGP w/viscous,” was evaluated using the AMY photon emission rate in the high-temperature (QGP) region and included viscous corrections to the photon emission rates [21,48] due to both bulk and shear viscosities. The same calculation without the viscous corrections corresponds to the curve labeled “QGP, w/o viscous.” Once viscous corrections are included, $v_2$ drops by more than 50% at 3 GeV/$c$, while the yield decreases just by ~10%. The third curve, labeled “semi-QGP, w/o viscous,” shows the consequence of including the effect of confinement on the photon emission rate, as computed in the semi-QGP approach [14]. The utilization of the semi-QGP photon rates at high temperatures suppresses the spectrum, but does not change the $v_2$ significantly. This is a consequence of the small contribution of QGP photons to the thermal photon $v_2$, which is dominantly produced at temperatures around and smaller than the confinement temperature. The prompt photon contributions in all three calculations are evaluated within the pQCD framework.

Third, we compare the data with PHSD (parton-hadron-string dynamics), a microscopic transport model [13]. In
addition to the traditional QGP and HG sources (resonance decays) this model includes late stage meson-meson and meson-baryon Bremsstrahlung, which enhances the yield at the lowest \( p_T \) substantially and increases \( v_2 \) by almost 50\% in the \( p_T < 3 \) GeV/c region (see Fig. 2 in Ref. [13]). Contributions from photonic decays of \( \phi \) and \( a_1 \) are also included, because these are not subtracted in the measurement. After all other sources are added, the direct photon spectrum is very well reproduced below 3 GeV/c, but \( v_2 \) underpredicts the measured values. Also, the \( p_T \) where \( v_2 \) reaches its maximum is under predicted. In Fig. 9 the data are compared to the latest PHSD model calculation [49] that included additional photon production channels in the hadronic phase and improved the Bremsstrahlung calculation. The model also provides \( v_3 \). It is positive and consistent with the data within uncertainties.

Explaining the large yield and strong flow simultaneously requires significant improvements in quantifying the contributions from the late stage QGP and HG interactions. Even deeper insight on both the photon sources and the time profile of the system may be necessary to further improve the models. Future measurements of more differential quantities will help to distinguish and quantify the individual photon sources.

V. SUMMARY AND CONCLUSIONS

The PHENIX experiment at the Relativistic Heavy Ion Collider measured second- and third-order Fourier coefficients of the azimuthal distributions of direct photons emitted at midrapidity in \( \sqrt{s_{NN}} = 200 \) GeV Au+Au collisions, for various collision centralities. Two different and independent analyses are used to determine the inclusive photon yield. The external conversion photon measurement allows one to extend the \( p_T \) range down to 0.4 GeV/c compared to 1.0 GeV/c for the calorimetric measurement. In the overlap region the two results are consistent. The \( v_2 \) measurements are also consistent with earlier published results, while \( v_3 \) is published for the first time.

Both the direct photon \( v_2 \) and \( v_3 \) are found to be large. The \( v_2 \) exhibits a clear centrality-dependence, while \( v_3 \) is consistent with no centrality dependence. At all centralities, the direct photon \( v_2 \) is similar in magnitude to the hadron \( v_2 \) for \( p_T < 3 \) GeV/c. The direct photon \( v_3 \) is consistent with that for hadrons over the entire \( p_T \) range.

We compare the data to several recent calculations, which treat the direct photon yields and the azimuthal asymmetries in a consistent production and evolution framework. None of them describe the full systematics of the data adequately, but there has been progress in the last few years. The general trend of the models appears to be including sources from the earliest (pre-equilibrium, see for instance Ref. [15]) or very late times in the evolution of the system, while giving less emphasis to photon production at intermediate times, when most of the expansion occurs. PHSD includes new sources from the HG and photon production even after the hadrons are decoupled from each other, which improves description of the yields but still under predicts \( v_2 \). The model that best approximates the measured \( v_2 \), including the \( p_T \) region where \( v_2 \) reaches its maximum value, starts the evolution with a large initial boost even before thermalization [12]. It is also worth noting that the microscopic transport model [13] is able to describe the anisotropies as well as the full-scale viscous hydrodynamics [14].

While the data are getting more differential and more accurate, and model calculations improve, the “direct photon puzzle” remains unresolved. High-quality data of yields and \( v_2 \) and \( v_3 \) for different collision systems, including very asymmetric ones, and energies would help to further improve our understanding of direct photon production because robust models must be able to describe the data over a wide range of experimental conditions.
